- Matthias Egger
- Jonathan Sterne

Outline

- Methods to be compared
- Nine example diagnostic meta-analyses
- Results
- Summary

Methods to compare

1. Separate random-effects meta-analysis of logit-transformed sensitivity and specificity, using:
 - a) Empirical logit-transforms Stata: `meta`
 - b) Random-effects logistic regression Stata: `xtlogit`
 2. SROC curve by linear regression
(Moses-Littenberg method)
} SAS: `NLMIXED`
 3. Bivariate
 4. HSROC

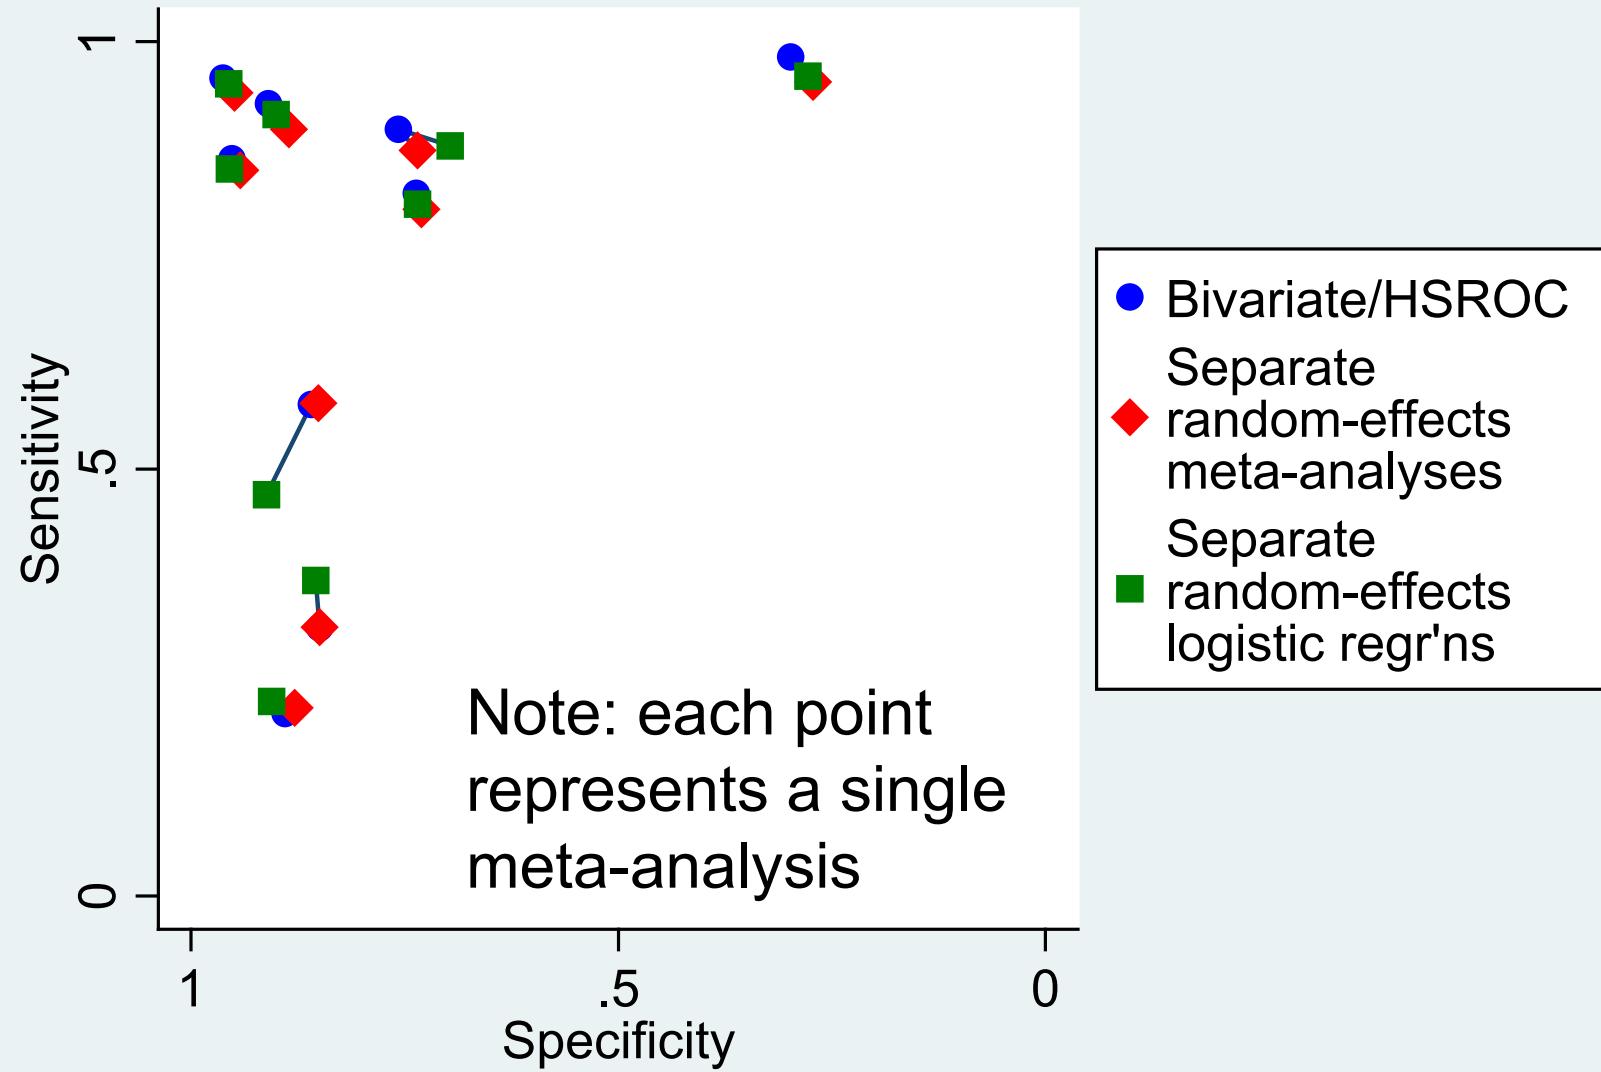

9 example meta-analyses

Test	Target Condition	No. of studies
Bacterial vaginitis	Pre-term birth	11
B-type natriuretic peptide	Heart failure	20
CT scan	Appendicitis	50
Electrocardiography	Left ventricular hypertrophy	17
Fetal fibronectin	Pre-term birth	21
Ottawa ankle rules	Fracture of the ankle / mid-foot	14
Alvarado prediction rules	Appendicitis	14
Scintigraphy	Appendicitis	28
Ultrasound	Appendicitis	141

Results

- Summary points
- Summary ROC (SROC) curves

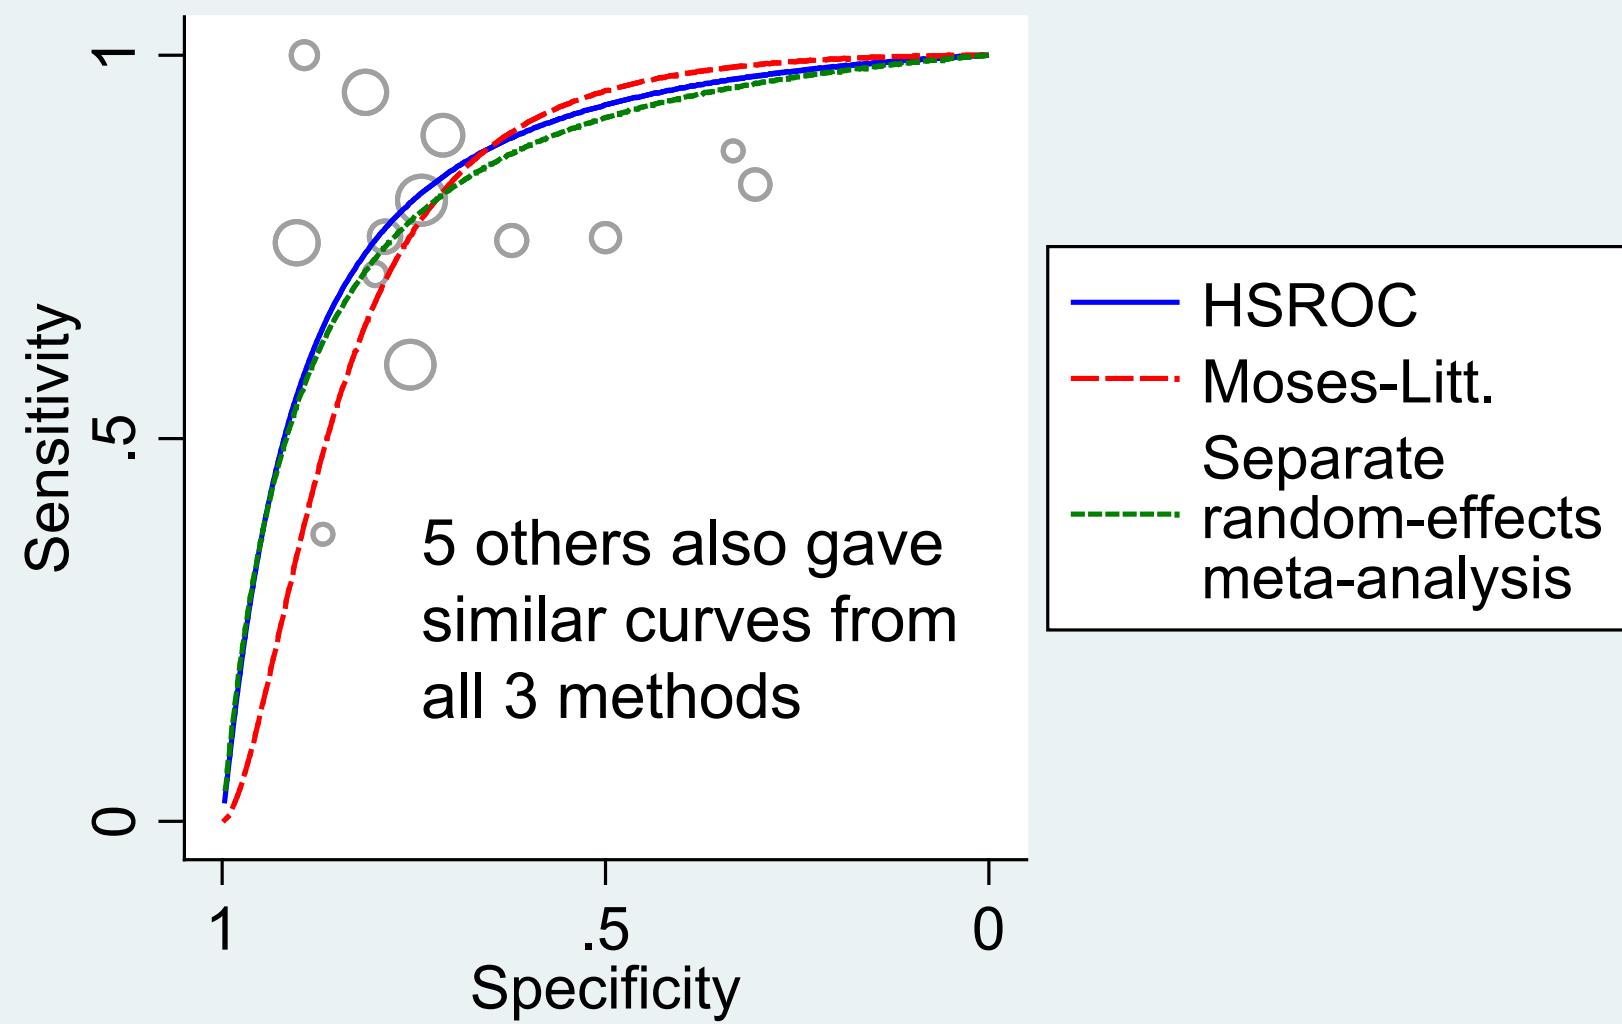

Comparison of summary points

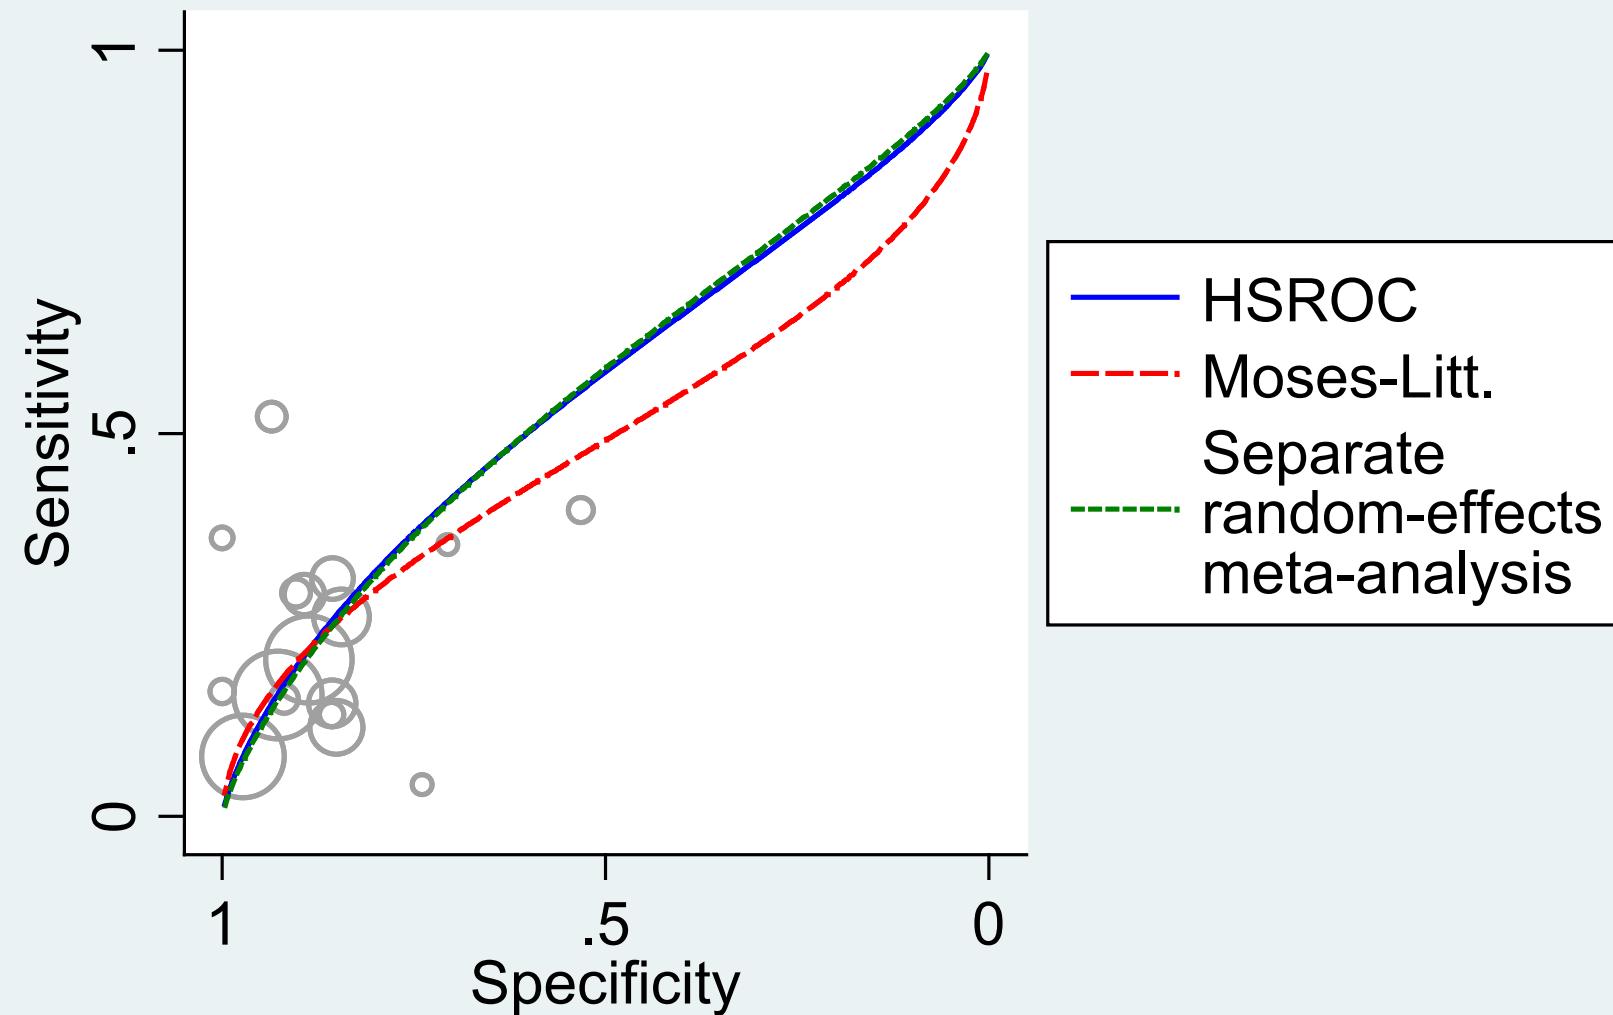

Summary curves

- Four examples:

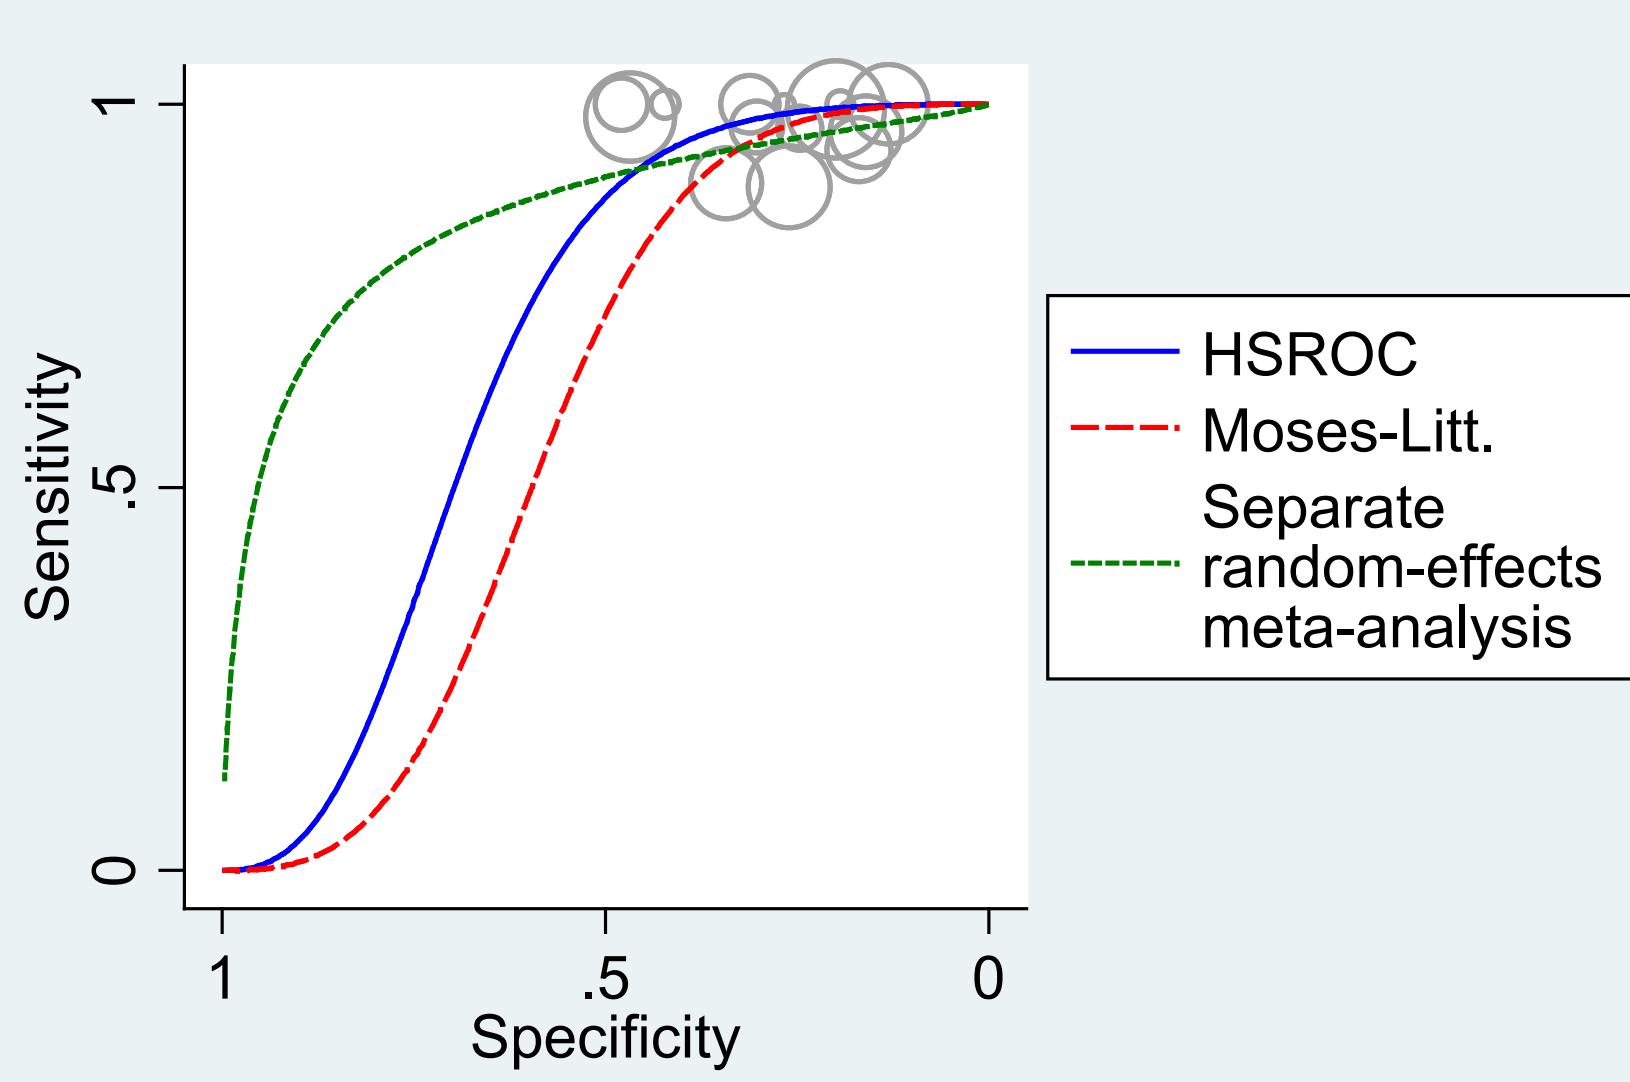

Alvarado prediction rules for appendicitis

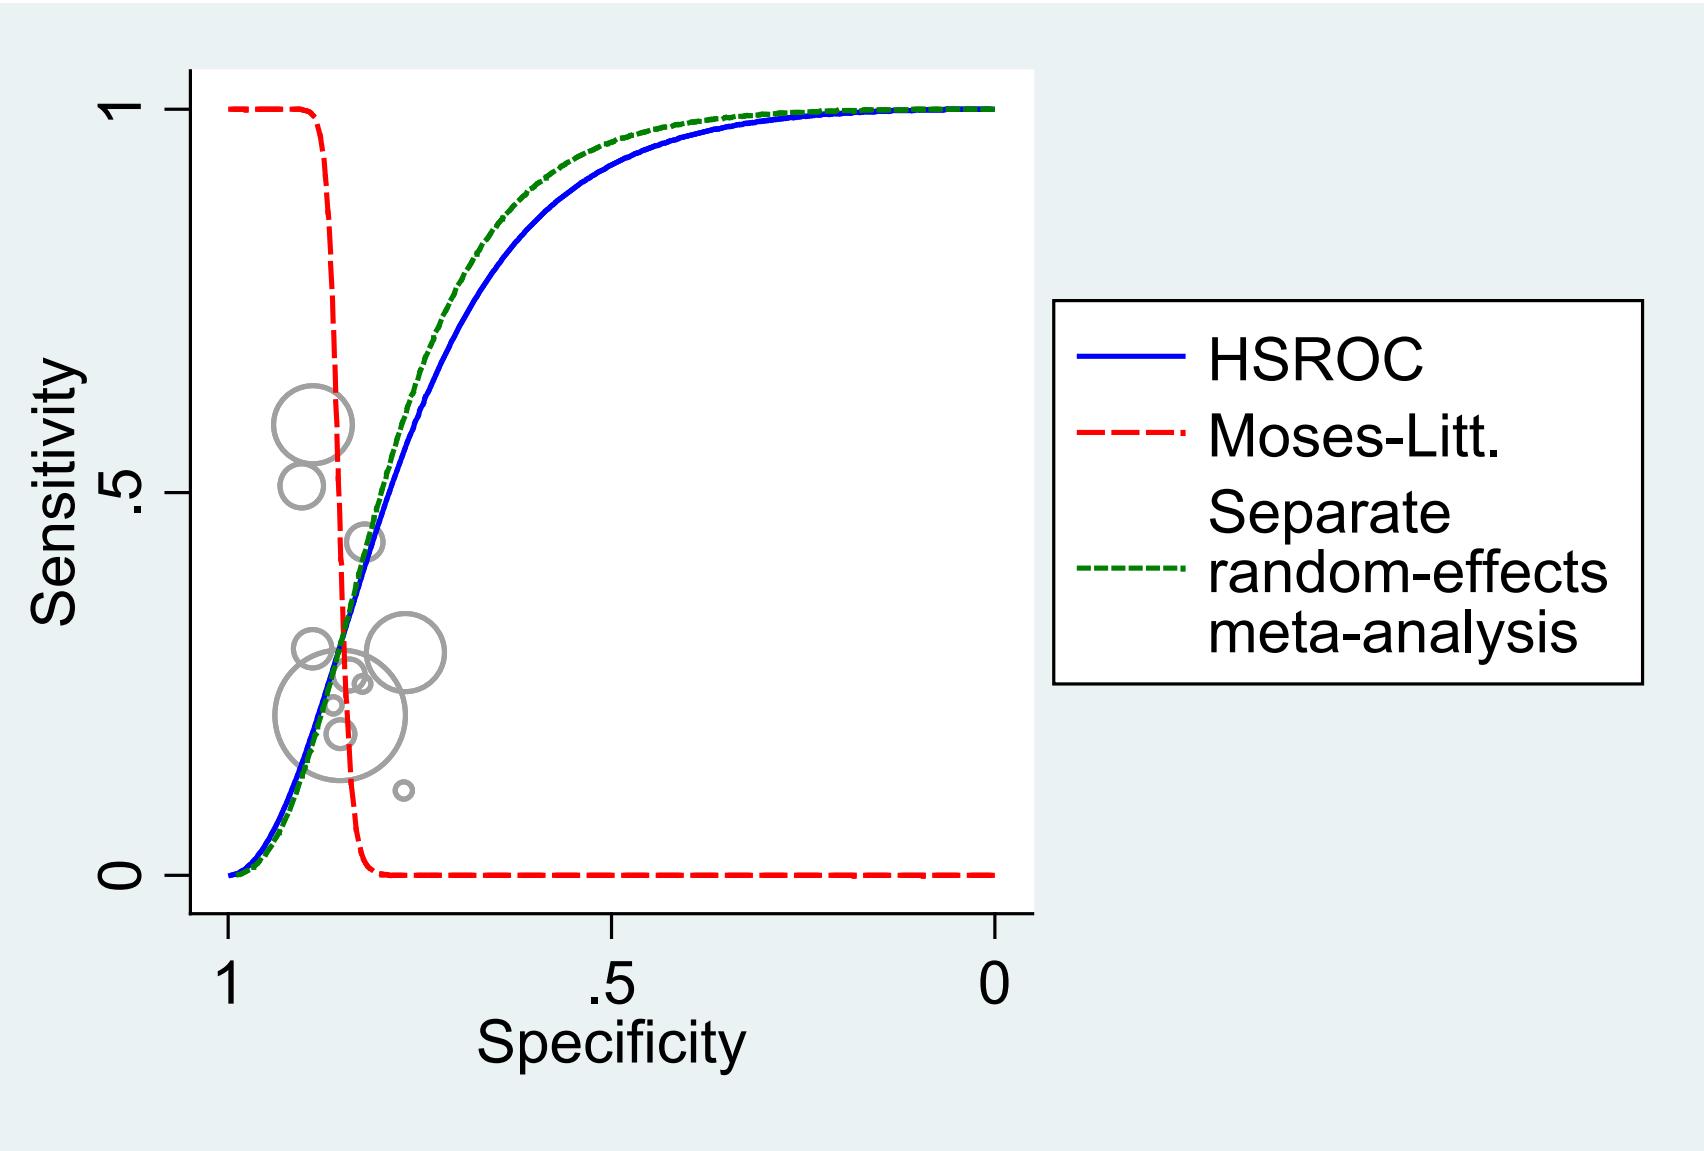

Electrocardiography for left ventricular hypertrophy

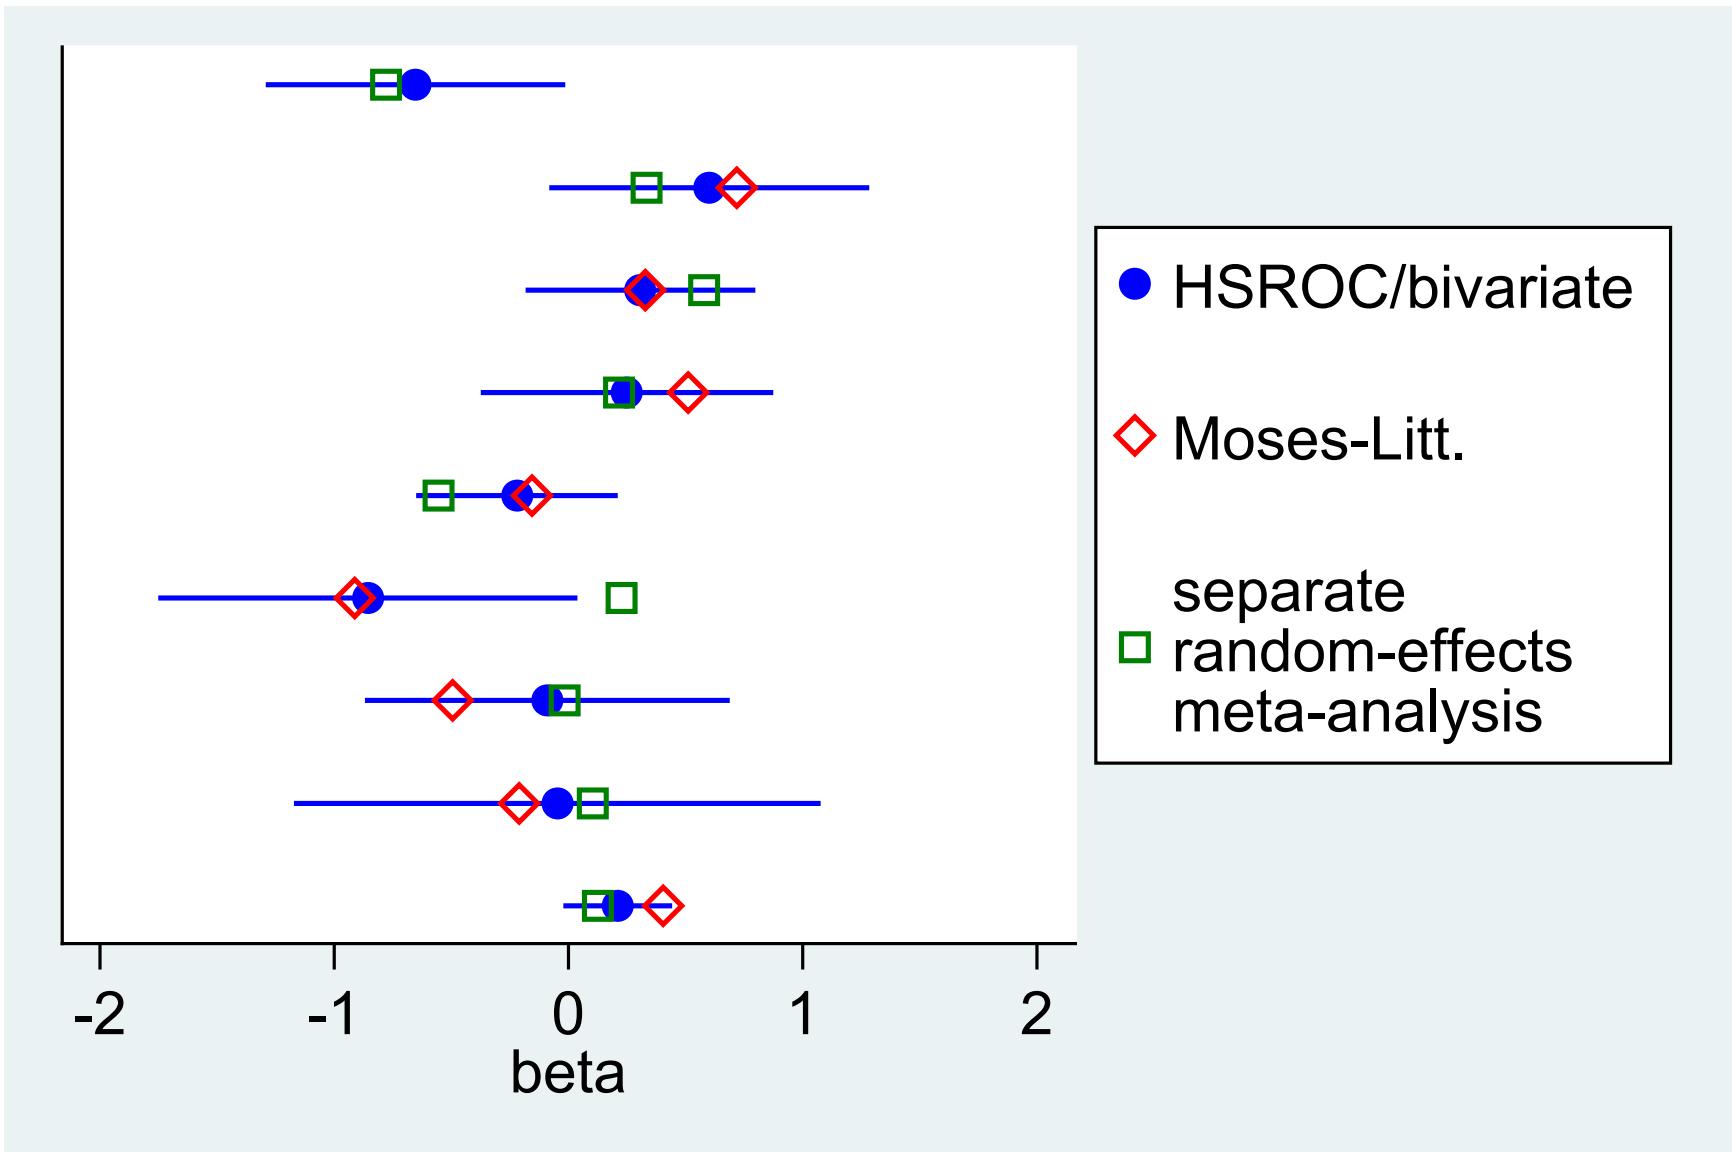

Ottawa ankle rules for fracture of ankle or mid-foot

Bacterial vaginitis for pre-term birth

Comparison of shape parameter (beta of HSROC model)

Summary: comparing non-iterative methods to HSROC/bivariate model

Method	Summary operating point	SROC curve
Moses-Littenberg	N/A	OK if don't extrapolate
Separate random-effects meta-analyses	Good	OK if don't extrapolate

Results from random-effects logistic regression appear less consistent

Final thoughts

- Often little information on shape (scale / asymmetry) parameter even with many studies
- Heterogeneity widespread in *all* dimensions
 - a prediction region may be more appropriate than a confidence interval/region for the summary point
- More experience with methods is needed
